Abstract

A homing pigeon (*Columba livia domestica*) was referred to the mycology laboratory of the Faculty of Veterinary Medicine, Ferdowsi University of Mashhad, Iran with the presence of ulceration, bleeding, loss of feathers and scabs and crust in the head region. Mycological evaluation was shown simultaneous infections by *Malassezia* and *Microsporum gallinae*. Pathological findings revealed severe and deep necrotic skin lesions associated with fungal hyphae and especially numerous yeasts. It was concluded that keratinophilic fungi, especially dermatophytes in skin and feathers of birds can cause severe lesions and be a potential source of spread of disease in the human population and animals. It also suggests considering the role of *Malassezia* spp. as a risk factor in the development of skin lesions and the emergence and exacerbation of infections such as dermatophytes.

Abbreviations

sp. and spp.: Species
*M. gallinae*: *Microsporum gallinae*
KOH/DMSO: Potassium Hydroxide/Dimethyl sulfoxide
μm: micrometer
Introduction

Skin and feather problems are common disorders in avian species (Schmidt and Lightfoot, 2005). Bird’s skin and feather lesions and their inflammation due to various fungi such as Candida sp., Aspergillus sp., Malassezia sp., Geotrichum candidum, Microsporum gallinae, Rhodotorula sp., Penicillium cyclopium and various other species have been described (Dahlhausen, 2005; Shivaprasad, 2008).

Decomposing skin and feathers of birds are known as carrier of microorganisms, especially pathogenic fungi which are capable to infect humans and animals (Miljkovic et al., 2011). Skin and feathers are a rich source of keratin and are regarded as one of the reservoirs of keratin-degrading microorganisms. Some of these keratinophilic fungi are species of dermatophytes known to cause cutaneous infections of keratinized tissues, viz. skin, feather, hair and nail (dermatophytoses) of humans and animals (Gungnani et al., 2012).

Microsporum gallinae (M. gallinae) is a dermatophyte that causes favus of the comb in chickens and related species (Murata et al., 2013). This fungal species also infects dogs (Baudet, 1943; Georg et al., 1962; Dvorak and Otcenasek, 1964; Komarek and Wurst, 1989), monkeys (Gordon and Little, 1968), cats (Dvorak and Otcenasek, 1964; Korting and Zienicke, 1990), squirrels (Georg et al., 1962), mice, canary, pigeon, and turkey (Chermette et al., 2008), and has been isolated from birds’ nests (Goodenough and Stallwood, 2010).

White crusts or plaques containing fungal elements are associated with hyperkeratosis, and lesions may spread to the skin of the head and the neck with feather loss, although the feathers are not invaded. Based on 44 reports, it would appear that the endemic areas of M. gallinae include European, Middle Eastern, and South American countries, in addition to the USA (Takahashi et al., 2003), Sweden, France, Germany, Czechoslovakia, Spain, Germany, Pakistan, Iran, Nigeria, Puerto Rico, Venezuela, and Japan (Miyasato et al., 2011).

Recent research indicates that Malassezia spp. and other fungi may play a role in some cases of dermatitis or feather picking. Malassezia spp. is occasionally found as an etiologic agent, generally documented on cytology or histopathology, for feather loss and dermatitis (Schmidt and Lightfoot, 2005).

To the best of our knowledge, there is no report on severe and deep necrotic skin lesions due to simultaneous infections by Malassezia and M. gallinae in homing pigeon in the world and in this manuscript, mycological, gross and histopathological aspects of the case are reported from Mashhad, Iran.

Case presentation

A homing pigeon (Columba livia domestica) was referred to the mycology laboratory of the Faculty of Veterinary Medicine, Ferdowsi University of Mashhad, Iran. The clinical signs included the presence of ulceration, bleeding, loss of feathers and scabs and crust in the head.

Sample collection from the skin lesions were done by a sterile scalpel. Direct microscopic examination was carried out on the samples mounted in 20% KOH/DMSO (Merck Co., Darmstadt, Germany). Also, the samples were cultured on Mycosel agar (Merck Co., Darmstadt, Germany) and modified Dixon agar containing 0.05% chloramphenicol (Merck, Darmstadt, Germany) and 0.05% cycloheximide (Sigma, St Louis, MO, USA). Plates were then incubated aerobically at both 25°C and 31°C for 2-4 weeks and were monitored daily.

For histopathological examinations, samples of the head lesions were taken and fixed in 10 per cent buffered formalin and processed according to the standard histological techniques for paraffin embedding. Tissue sections 5 μm thick were prepared and used for conventional hae-
matoxylin–eosin and special Periodic Acid Schiff (PAS) staining methods.

Results and Discussion

Hyaline septate branching mycelium and arthroconidia were observed during direct examination of skin samples. Colonies grown on Mycosel agar were flat with a suede-like texture and white in color with strawberry-colored pigmentation diffusing into the medium. Subsequently, the colonies were examined under the light microscope after staining with lactophenol cotton blue. Septate hyphae with small numbers of macroconidia consisting of 4–6 cells (4–7 × 12–18 μm) and ovoid to pyriform, single-celled microconidia (1–2 μm in diameter) attached to the hyphae at right angles were observed. Macroscopy and Microscopy results from culture revealed the presence of Microsporum gallinae (M. gallinae).

Microscopic examination from colonies grown on modified Dixon agar determined numerous spherical or oval-shaped yeasts with unipolar budding and a distinct collar, typical of Malassezia sp.

Histopathological examinations of the head skin lesions revealed ulcer and crust formation, hemorrhages, hyperemia and superficial epidermal necrosis and tissue debris (Figure 1). Diffuse necrotic dermal lesions were observed beneath the skin ulcer. Some sequestrated necrotic areas were seen in subcutaneous that were surrounded by infiltrations of mixed inflammatory cells, including macrophages, lymphocytes and plasma cells. Fungal hyphae and especially numerous yeasts were found in the central parts of these subcutaneous necrotic areas (Figure 2A). In PAS stained sections, the fungal structures were purple in color and seen in the superficial keratin layer adjacent to the ulcers and also were associated with the central parts of subcutaneous lesions (Figures 2B and 3).

Cutaneous lesions in birds may be due to nutritional deficiencies, external parasites, microbial agents, and etc. Fungal dermatitis is rarely reported in birds. Infections of the integument caused by Candida albicans, Rhodotorula, M. gallinae, Aspergillus, Rhizopus, Malassezia and Mucor species have been described (Dahlhausen, 2005; Shivaprasad, 2008). Skin and feather lesions associated with Aspergillus have been recognized in pigeons and psittacine birds (Tudor, 1983); but to our knowledge, there is no report on severe and deep necrotic skin lesions due to simultaneous infections by Malassezia and M. gallinae in homing pigeon that the present article describes.

M. gallinae is the principal dermatophyte of gallinaceous species, and is associated with a white crust on the comb and wattles ("fowl favus"). Microsporum sp. has been documented as a cause of dermatologic problems in the duck, pigeon and canary (Ritchie et al., 1994). Histologic lesions included hyperkeratosis of the epidermis with invasion of the stratum corneum by fungal mycelia, acanthosis, acantholysis, and hydropic degeneration of cells in the stratum corneum. The underlying dermis was infiltrated by mononuclear inflammatory cells and contained lymphoid foci. Fungi can also be seen in the feather follicles associated with hyperkeratosis (Shivaprasad, 2008).

Occasionally birds are seen with superficial infections by yeasts morphologically resembling Malassezia (Schmidt et al., 2015) The genus Malassezia lives on the surface of the skin and mucous membranes of some mammals and birds; is a commensal organism that may eventually act as a pathogen. Changes in the host's skin microenvironment and immune problems can cause colonies to act as opportunistic pathogens (Brasao et al., 2015). Gross changes are usually not seen in psittacine birds, and, in small passerines, they are nonspecific, with some flaking, thickening of the skin, and possible reddening, particularly if there is pruritis and self-trauma. In psittacine birds, there is usually a minimal perivascular dermal inflammatory infiltrate comprised primarily of lymphocytes and plasma cells, with

organisms found in the keratin. Small passerine birds may have significant superficial dermatitis, with a pleocellular infiltrate (Schmidt et al., 2015). Malassezia spp. and M. gallinae have been reported in birds; so that the most skin lesions caused by them appear in the superficial epidermis, hair follicles epithelial cells or associated dermis. In this study, severe and deep necrotic skin lesions were associated with fungal hyphae and especially numerous yeasts but there was no lesions and fungal structures in the feather follicles.

In conclusion, the results of the present case shows that keratinophilic fungi, especially dermatophytes in skin and feathers of birds can cause severe lesions and be a potential source of spread of disease in the human population and animals. It also suggests considering the role of Malassezia spp. as a risk factor in the development of skin lesions and the emergence and exacerbation of infections such as dermatophytes.
